Abstract

Because most data processing systems are distributed in nature, data must be transferred between machines. Currently, Spark, a prominent such system, predetermines the strategies for shuffling this data, but in certain situations, different shuffle strategies would improve performance. We add functionality to track metrics about the data during the job and appropriately adapt the shuffle strategy. We show improvements in ShuffledRDD performance, joins using Spark's RDD interface, and joins in Spark SQL.

Acknowledgments

First, I would like to thank my parents Umesh Mahajan and Manjula Mahajan for their enduring support and love throughout my time at MIT.

I would like to thank Professor Matei Zaharia for his guidance, patience, and support while advising me throughout this project. I learned a lot throughout this project and am extremely grateful for the support.

At MIT, my work would never have been completed if not for the support of my friends. I would like to thank them for all the lessons that I have learned and all of the memories that I have created.

Chapter 1

Introduction

1.1 Spark and MapReduce

New data processing systems such as Spark and MapReduce have been designed to help process the increasing amount of data [2] [5]. Instead of relying on just one powerful computer, these systems use many computers due to lower costs, increased scalability, and improved fault tolerance. Because these systems are distributed in nature, they have stages (shuffle stages) where they transfer information between computers.

1.2 Shuffle

We will use MapReduce to explain the shuffle in more detail, but the main concepts still apply to Spark.

1.2.1 Shuffle Introduction

In the first stage of MapReduce, the map phase, the data is loaded onto different computers and computation is performed on it that results in a group of key-value pairs. The final phase of MapReduce, the reduce phase, assumes that all key-value pairs with the same key are grouped together onto the same machine. We call this property the shuffle guarantee. Thus, the shuffle phase, an intermediate phase that the system handles internally, transfers

key-value pairs between machines to satisfy the shuffle guarantee.

Figure 1-1 displays the inner workings of the shuffle phase. For instance, a programmer may want to count the number of letters in a distributed file. The mappers will each load part of the distributed file and count the number of letters in their part. However, the system needs to aggregate the count for each letter and thus all the counts for letter A will be sent to Reducer 1, letter B will be sent to Reducer 2, and letter C will be sent to Reducer 3. These reducers will then promptly aggregate the counts that they receive from the mappers.

Figure 1-1: Shuffle for Letter Count in MapReduce

This figure demonstrates a basic shuffle in MapReduce. Each mapper sends its letter counts to different reducers such that each reducer gets the total letter count for a specific letter.

Due to the huge amounts of keys, these systems do not transfer data on the granularity of keys. Instead, they use partitions, which contain key-value pairs with different keys. Programmers can pick different partitioning functions such as hash partitioning and range partitioning to map keys to partitions. Two identical keys are guaranteed to be in the same partition. As long as all the mappers partition their data in the same way and send each partition with the same index to the same reducer, the system satisfies the shuffle guarantee.

1.2.2 Shuffle Analysis

MapReduce is constrained by the slowest worker; therefore, minimizing the latency of the slowest worker should improve performance. Balancing the amount of data sent to each reducer helps achieve this by reducing both network latency and also the execution time for the slowest worker. Figure 1-2, depicts a shuffle scenario that results in unbalanced partitions. A basic heuristic is used with each reducer getting half of the mapper output partitions. Generally, this protocol should result in balanced reducers, but as seen, Reducer 2 receives twice the amount of data as Reducer 1. However, if the system knew the sizes of the map output partitions, it could more intelligently balance the reducers. As seen in Figure 1-3, with the same map output partitions, the system could attain complete balance of 60MB for each reducer.

1.3 Adaptive Scheduling of Joins

1.3.1 Join Basics

A common operation in these data processing environments is a join [3]. A join basically combines two tables by finding intersections between keys in respective columns. For instance, if we have Table 1.1 and Table 1.2 that we are trying to join based on the intersection of key1 and key2, the resulting output is Table 1.3

Key1	Value1
a	1
a	1
b	3
c	4

Table 1.1: Table for Dataset 1

Key2	Value2
a	5
c	7

Table 1.2: Table for dataset 2

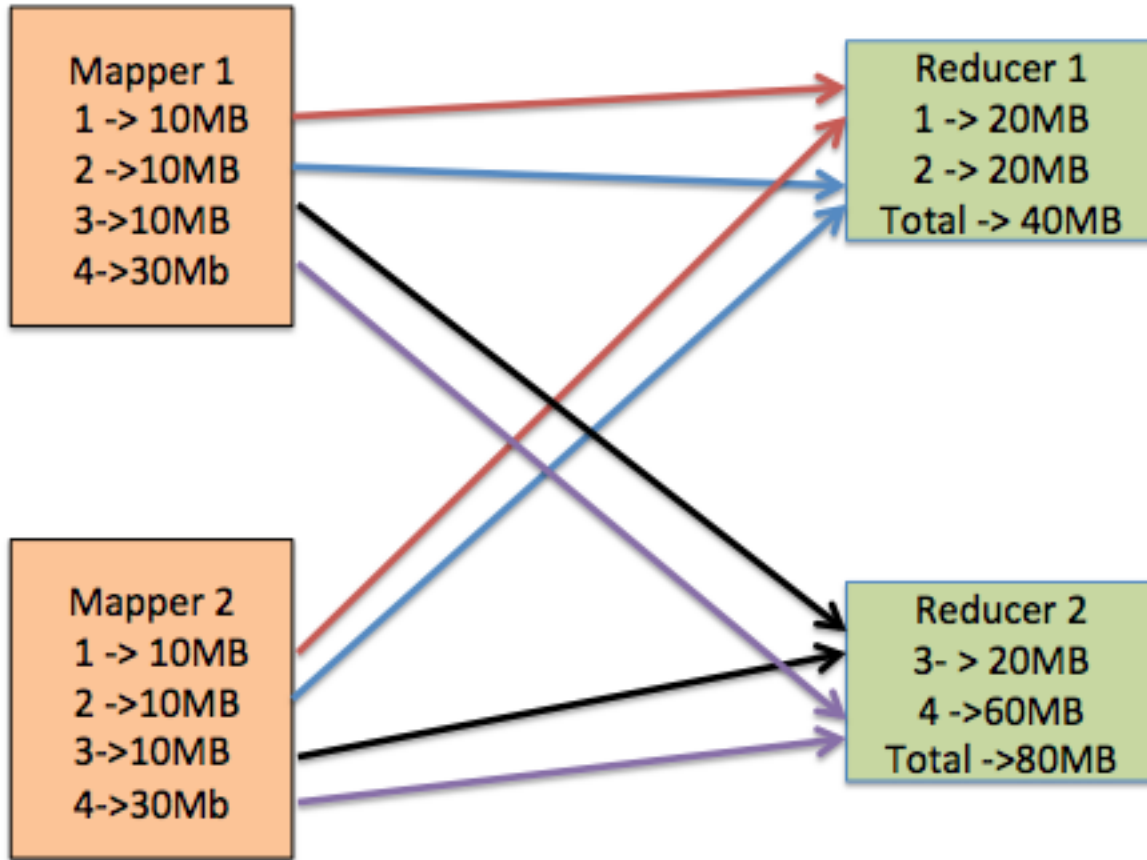

Figure 1-2: Unbalanced Shuffle

Reducer 1 requests partition 1 and 2 while Reducer 2 requests partition 3 and 4. This results in Reducer 2 receiving 80MB of data while Reducer 1 receives only 40MB of data.

Key1	Value1	Value2
a	1	5
a	2	5
c	4	7

Table 1.3: Table of Joined Data

1.3.2 Shuffle Join

The actual implementation of joins in MapReduce is very similar to the shuffle scenario presented above. Instead of having output partitions for just one dataset, the mappers have output partitions for two datasets and ensure that all partitions for both datasets with the same index are sent to the same reducer. Figure 1-4 details a shuffle join. For both datasets, all of the keys that mapped to partition 1 were sent to Reducer 1 and this happens respec-

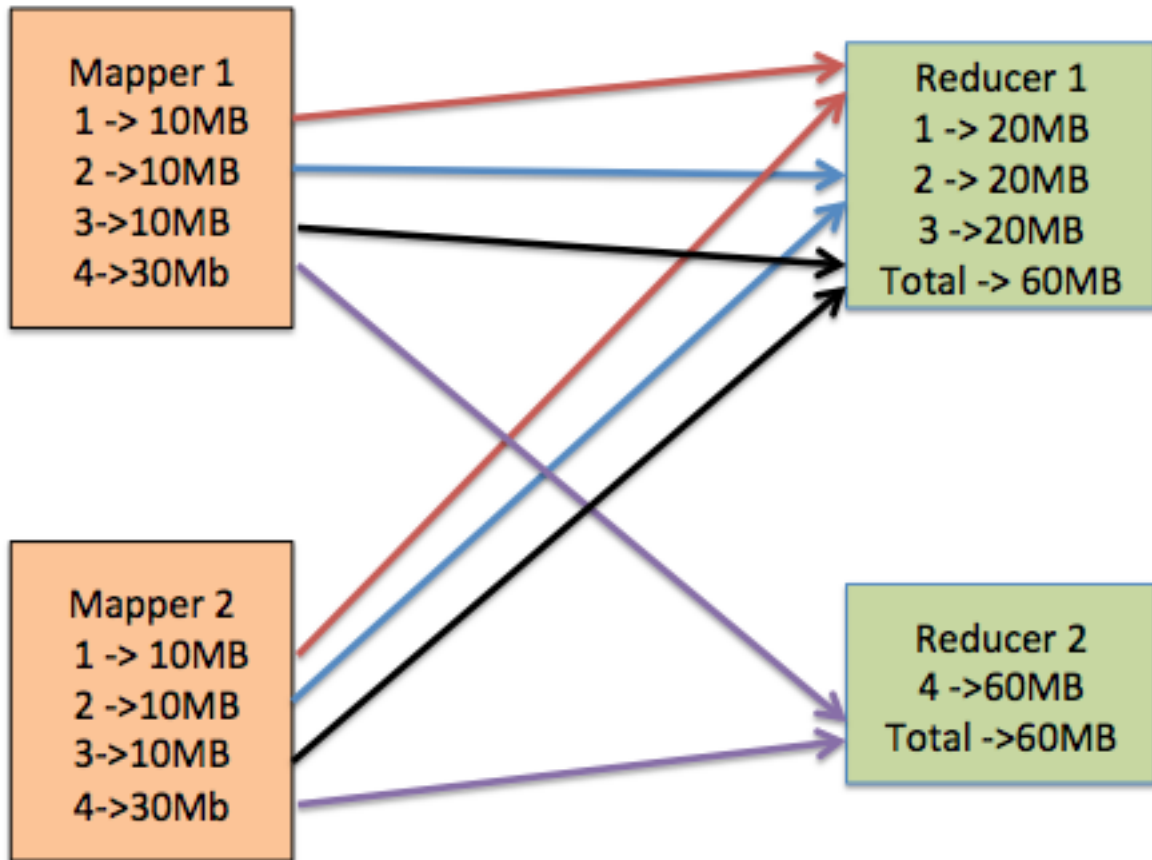

Figure 1-3: Balanced Shuffle

tively for the rest of the partitions. Because all identical keys are in the same partition and each partition with the same index is sent to the same reducer, the system is guaranteed to find all intersections required for the join.

1.3.3 Broadcast Join

The diagram above may seem to imply that mappers and reducers are different machines. However, this distinction is artificial and there are no separate machines for mappers and reducers. Therefore, not all data in the shuffle stage is transferred over the network. In Figure 1-1, if Mapper 1 and Reducer 1 were the same machine, the key-value pair A=7 would be read locally and not have to be received over the network.

Because transferring data over the network could be a bottleneck, the broadcast join tries to increase the amount of data being read locally [4]. For instance, in Figure 1-4,

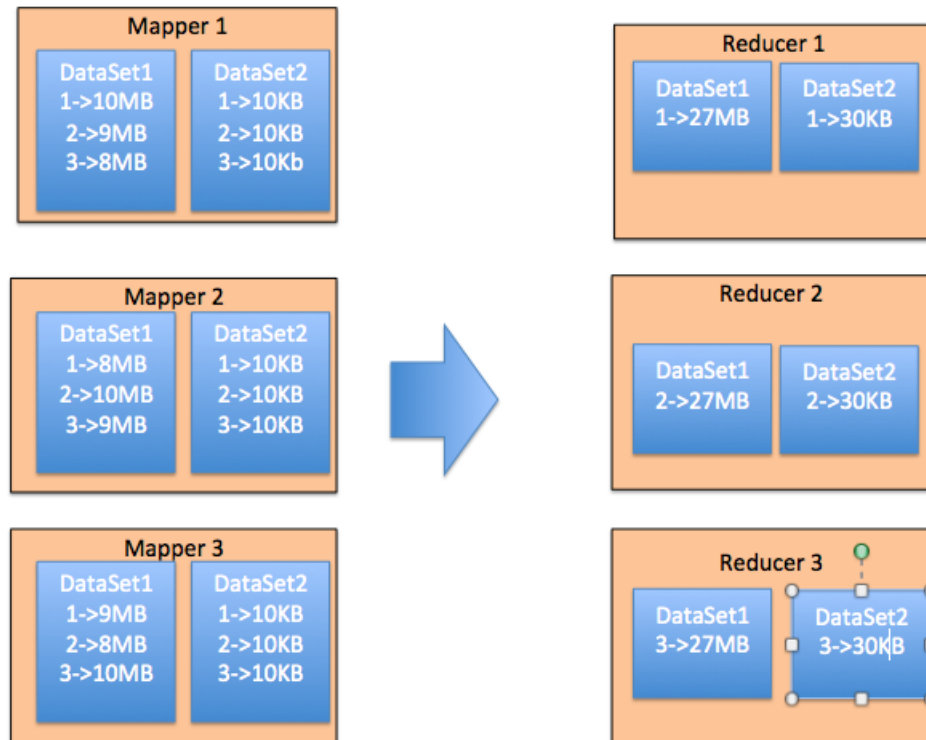

Figure 1-4: Typical Shuffle Join

This figure depicts a typical shuffle join. The mappers have output partitions for two different datasets. They ensure that all the partitions with the same index get sent to the same reducer. Reducer 1 received partition 1, Reducer 2 received partition 2, and reducer 3 received partition 3.

Dataset 1 is drastically bigger than Dataset 2. As seen in Figure 1-5, the broadcast join keeps the bigger dataset in place and sends the entirety of Dataset 2 to every reducer. Even though all of Dataset 1 stays in place, this method will still find all intersections between the datasets because all partitions of Dataset 2 are sent to every reducer. The diagram shows that only Dataset 2 is transferred and thus the network traffic is reduced from megabytes to kilobytes.

Broadcast Join is not always the optimal strategy. Because the entirety of the smaller dataset is sent to every partition, the amount of total computation time increases. Additionally, if the datasets are approximately the same size, network traffic will actually increase. Each join strategy is the optimal strategy in different situations. Thus, it becomes imperative to pick the strategy after the mappers have run and the size of the map output partitions is known.

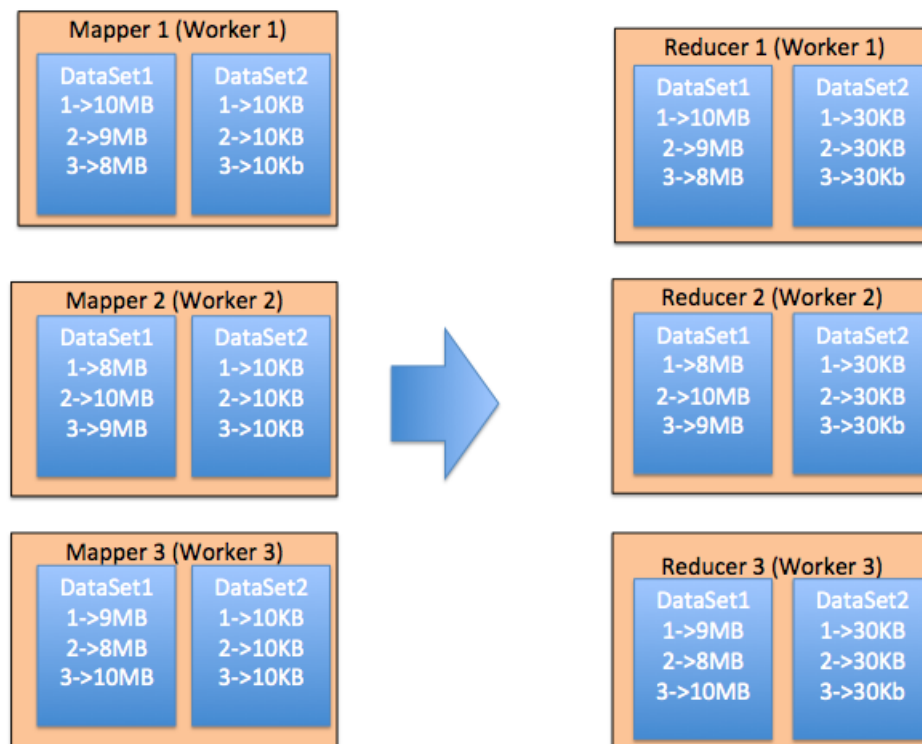

Figure 1-5: Broadcast Join

This figure depicts a Broadcast Join. As evidenced, the bigger dataset stays entirely in place but the entirety of the smaller dataset is sent to the each reducer. This cuts network traffic from megabytes to kilobytes.

Chapter 2

Implementation

2.1 Spark

All of the code was implemented in Spark but could also be implemented in MapReduce to achieve similar performance improvement. The Resilient Distributed Dataset(RDD) is the main programming interface within Spark. An RDD can be created from data or from another RDD. The key attributes of an RDD are its inputs, the number of partitions, and how each of its partitions is computed based on its inputs.

Profressor Matei Zaharia added code that allowed the tracking of sizes of map output partitions.

2.2 ShuffledRDD

The RDD we developed is a new version of ShuffledRDD, ShuffledRDD2. Its inputs are first a shuffle dependency, which is basically a bunch of map output partitions, and second, a number of reducers, or equivalently the number of partitions for ShuffledRDD2. In the regular ShuffledRDD, each of its partition naively requests a segment of map output partitions as depicted in Figure 1-2. ShuffledRDD2 implements the more complicated scheme seen in Figure 1-3. The current Spark API only allows reducer partitions to request consecutive map partitions. In other words, it is impossible for a ShuffledRDD2 partition to have map output partitions 1 and 3, without having 2. For this constraint and the given number

of reducer partitions, ShuffleRDD2 assigns map output partitions to optimally balance the number of bytes received by each of its reduce partitions.

2.3 Joins

2.3.1 ShuffleReader Changes

In the broadcast join, the bigger RDD must stay in place. The current interface only allows a reducer to request a specific map output partition from all of the mappers. For the bigger RDD, the system would then have to request map output partitions from other machines, which defeats the purpose of the broadcast join. Thus, we added the capability of requesting a specific partition from just one mapper.

2.3.2 ShuffledJoinRDD and BroadcastJoin RDD

We implement two different type of RDDs, the ShuffledJoinRDD and the BroadcastJoinRDD. Both of these RDD's take two shuffle dependencies, which remember are basically the outputs of map stages, partitioned in a certain way. These dependencies must be partitioned in the same way; otherwise, two identical keys would not map to the same partition index.

The ShuffledJoinRDD implementation is very similar to ShuffledRDD. Instead of fetching map output partitions from just one dependency, it fetches the corresponding map output partitions from both dependencies. The user specifies the number of ShuffledJoinRDD partitions and each partition requests a corresponding fraction of the map output partitions. For instance, ShuffledJoinRDD partition 1 will fetch Dataset1 Partition 1 and Dataset2 Partition 1 from all of the workers. Once these partitions are fetched, it creates a map with the key-value pairs of the smaller partition. Subsequently, it iterates through the keys of the bigger partition, seeing if they are present in this map, and if so, adding the intersection to the output.

The BroadcastJoinRDD implements the broadcast shuffle. For each BroadcastJoinRDD partition, it requests one local map output partition from the bigger RDD using the

new request capability and all of the partitions from the smaller RDD. The number of partitions is equal to the number of partitions of the bigger input RDD. We use the location preferences api of the RDD to ensure that the reducer partitions are placed on the same machines that the mapper partition it is requesting, to ensure data is requested locally instead of over the network. The system use the same strategy with the map and the iteration as the ShuffledJoinRDD to then find the intersections.

2.3.3 Joins in Spark SQL

Many programmers and data analysts prefer not to use the RDD interface and are more familiar with the SQL; thus, Spark offers a SQL like interface or SparkSQL [1]. One popular operation within SQL is join [2]. Although the user still writes in SQL, Spark still executes the code using RDDs.

Because we are not just using the RDD interface and Spark automatically converts the SQL query into a query plan, the implementation is much more complicated and thus we only implement our optimization for sort merge join. Although the exact semantics for how a sort merge join can be found here[6], the sort merge join still must shuffle data around as it requires that every key that could intersect should be sent to the same reducer. To help achieve this, the sort merge join applies an exchange operator on each of the map outputs. These exchange operators produce ShuffleRowRDDs, which for our purposes are equivalent to ShuffledRDDs. In the next stage, each partition in the first ShuffleRowRDD is compared to the partition with the same index in the second ShuffleRowRDD. The only difference between this and how the join RDDs work is pretty semantic in that instead of one RDD requesting partitions from multiple mappers, two RDD's repartition their data and then another one compares them partition by partition. By default, the code performs a shuffle join almost exactly in a manner with how the ShuffledJoinRDD works. One ShuffleRowRDD requests the corresponding partitions from its mappers just like Figure 1-2 and the other ShuffleRowRDD does the exact same but with its dataset.

However, if only one input RDD is smaller then a user-configured threshold, the system uses the broadcast join optimization. The bigger ShuffleRowRDD will be exactly

like its parent. We achieve this by setting number of partitions for the ShuffledRowRDD to be equal to its parent and then having each partition request a specific partition from the parent using the new request api and set its location preference accordingly. The other ShuffledRowRDD will have the same number of partitions as the bigger ShuffledRowRDD with each partition containing the entirety of the smaller input RDD. The correctness guarantees are the same as the BroadcastJoinRDDs.

Chapter 3

Experiment

3.1 Setup

All jobs were run using the spark interactive shell. All jobs were run ten times, with the last five times being averaged. All local jobs were run on a 2013 MacbookPro with 8GB of RAM and 2 cores. All distributed jobs were run using the spark/ec2 launch scripts. They were run on four AWS m1.large machines in the us west zone.

3.2 Regular Shuffle

We compared the performance of ShuffledRDD vs ShuffledRDD2 both on a local machine and on a distributed cluster.

For the local machine test, we created four mapper partitions. One of these mapper partitions was three times the size of the other mapper partitions. We created two reducer partitions. For the regular ShuffledRDD, each reducer gets two mapper partitions, which results in one reducer partition having twice the amount of data. For the ShuffledRDD2, one reducer requests the three bigger map partitions while the other gets one map partition, resulting in balanced partitions. We graph the total amount of data in versus time. As seen in the graph, the ShuffledRDD2 performs better as it has more balanced reducers.

For the reducer test, we created 64 mapper partitions. One of these mapper partitions was way bigger and equal to 8 regular mapper partitions. We had eight reducers. In the

Figure 3-1: ShuffledRDD vs ShuffledRDD2

This figure measures the performance of joins completed using the ShuffledRDD versus the ShuffledRDD2. The ShuffledRDD is in red while the ShuffledRDD2 is in blue. In the ShuffledRDD, reducer 1 gets twice the amount of data as in reducer 2, but in the ShuffledRDD2 receive the same amount of data. The x axis indicates how much data was shuffled.

ShuffledRDD, one of these reducers had twice the amount of data as the others, in the ShuffledRDD2 they were all balanced.

3.3 Broadcast and ShuffleJoinRDD

For this test, we created a bigger RDD with key-value pairs of $(x, 2 * x)$ with x ranging from 1 to 100 million. As seen in the Figure 3-3, we then then manipulated the number of key-value pairs of the smaller RDD, with each key value pairs being (x,x) . We measured the performance for the ShuffleJoinRDD and BroadcastJoinRDD on AWS. As expected, initially the BroadcastJoinRDD performs better as it requires significantly less network traffic. However, it soon becomes slower then the ShuffleJoinRDD as the smaller input RDD increases. Increasing the smaller RDD does not dramatically influence the ShuffleJoinRDD as it is more bottlenecked by the bigger RDD and just sends pieces of the smaller RDD

Figure 3-2: ShuffledRDD vs ShuffledRDD2

This figure measures the performance of joins completed using the ShuffledRDD versus the ShuffledRDD2. The ShuffledRDD is in red while the ShuffledRDD2 is in blue. We had eight reducers. In the ShuffledRDD, one reducer gets twice the amount of data as the other reducers, but in the ShuffledRDD2 they all receive the same amount of data. The x axis indicates how much data was shuffled.

to each partition. However, this increase significantly influences the BroadcastJoinRDD because transmits the entirety of the smaller RDD to every partition.

3.4 Spark SQL join

Figure 3-3: BroadcastJoinRDD vs ShuffledJoinRDD

This figure measures the performance of joins completed using the BroadcastJoinRDD versus the ShuffleJoinRDD. The BroadcastJoinRDD is in blue while the ShuffleJoinRDD is in red. The bigger RDD is fixed with 100 million key-value pairs, but the number of key-value pairs of the small RDD is manipulated along the x axis.

Chapter 4

Future Research and Conclusion

4.1 Future Research

4.1.1 Extension of Shuffle

ShuffledRDD2 is limited in a couple ways. First, each reducer can fetch multiple partitions, but these partitions are internally fetched individually. Batching these partition request together could help reduce overhead. Second, the current version only supports inputting the number of reducers. Users could prefer an interface where they input the maximum number of bytes a reducer can have and then system automatically determines the number of reducers.

4.1.2 Extension to Join

First, we implement our changes in the exchange framework to make the easiest possible change to allow for our optimization, but we could conceivably do this in a cleaner manner.

Second, users have to statically pass in thresholds that determine when to switch between broadcast and shuffle joins. The system should automatically determine this based on factors such as the size of the input RDDs, the network bandwidth, and the memory of each machine.

Third, we either broadcast an entire RDD or default to the shuffle pattern. However, if RDD1 has a big partition 1 and a small partition2 and RDD2 has a small partition 1 and big

partition 2, the system performs a shuffle. However, the system could save time by having RDD1 broadcast its partition 1 and RDD2 broadcast its partition 2.

Fourth, in the broadcast join in Spark SQL, each ShuffleJoinRDD partition requests the entirety of its input. This request is made over the network for each partition, but generally multiple ShuffleJoinRDD partitions are on the same machine. Thus, a request should be made once per machine and stored in memory for the other partitions to use.

4.2 Conclusion

In conclusion, we show that improvements can be made to shuffle stage of Spark. Instead of predetermining our shuffle strategy, we can adapt it based on the output of the mappers. We show that these strategies improve the regular shuffle RDD, joins with RDDs, and joins in Spark SQL. Although we have shown improvements, the work can be extended with simple changes to further improve performance.
